Many neurobehavioural and neuroendocrinological effects of excessive neural stem proliferation in human fetal and neonatal life have been identified. However, we are still at the beginning of our understanding of whether enhanced cell proliferation per se is advantageous to the developing individual. Some of the long-term effects of protracted early life neural cell proliferation are growth retardation, reduced adult size, and metabolic disorders. However, other long-term outcomes are apparent. Evidence indicates that excessive cell proliferation results in the production of cytokines and growth factors that stimulate growth and enhance the survival and repair of damaged neural tissue, and these factors may contribute to the pathogenesis of adult neurodegenerative diseases. Recent epidemiological and cohort studies have identified associations between prematurity, reduced growth and development, and impaired growth and cognitive development in later life. The findings from this body of research suggest that protracted early life neural cell proliferation may be adaptive. The most obvious and severe long-term threat to survival is from preterm birth, but there are alternative risks. A short gestation exposes the neonate to the constant challenge of limited oxygenation and inadequate nutrient supply. At the same time, there is no (or
